2016HO09 searched for production of element 120 using the $^{248}Cm(^{54}Cr,3n)$ reaction at GSI. Three correlated $\alpha$ decays were observed, followed by a high-energy event which could be spontaneous fission, were observed. The energy and decay time of the final $\alpha$ decay are in agreement with the properties of $^{291}Lv$. However, an implantation event could not be identified unambiguously. The time between the final $\alpha$ decay and the potential spontaneous-fission event is also much longer than most other published data.

2017HE11 presents a reanalysis of the data in 2016HO09 and concludes that the three events are background events rather than a decay chain.
